High Throughput Screening of 3D Printable Resins: Adjusting the Surface and Catalytic Properties of Multifunctional Architectures

Abstract

Identification of 3D printable materials is crucial to expand the breadth of physical and chemical properties attainable by additive manufacturing. Stereolithography (SLA), a widespread 3D printing method based on resin photo-polymerization, is ideally suited for exploring a large variety of monomers to produce functional three-dimensional solids of diverse properties. However, for most of the commercially available SLA 3D printers, screening monomers and resin compositions requires large volumes (~150 mL) in each printing cycle, making the process costly and inefficient. Herein, a high throughput block (HTB) adaptor was developed to screen arrays of monomers and resin compositions, consuming lower volumes (< 2 mL) and less time per print (< 1/16 based on a 4?4 matrix) than using the original hardware. Using this approach, a library of materials with different surface hydrophobicities were 3D printed by including long chain acrylates in the resins. In addition, several metal salts were dissolved in an acrylic acid-based resin, 3D printed and screened as heterogeneous catalysts for the selective aerobic oxidation of benzyl alcohol to benzaldehyde. Cu(II)-based resins produced the most active structures. Combinations of Cu(II) and long chain acrylate monomers were then used to 3D print complex catalytic architectures with varying degrees of hydrophobicity. Linear relationships were observed between 3D printed surface area, surface hydrophobicity and catalyst performance. For a high surface Schwarz P topology ca. 60 % enhancement in the catalytic activity of Cu(II) was attained by replacing the parent resin with one containing hydrophobic isodecyl groups, indicating that the immediate environment of the catalytic site affected its performance. The HTB enables fast screening of resins for 3D printing multifunctional architectures with intrinsic catalytic activity, tunable surface properties, and minimal waste.

INTRODUCTION

3D printing is a novel technology to manufacture custom objects with intricate architectures directly from computer-based designs. In many cases these three-dimensional structures are too difficult to produce with traditional methods. The ability to 3D print materials with suitable properties has led to several applications in diverse fields like tissue engineering,¹⁻⁴ electronics,⁵ ceramics,⁶⁻⁹ mechanical devices,¹⁰⁻¹⁶ pharmaceuticals,¹⁷⁻²⁰ periodic microstructures,^{6,21} and catalysis.²²⁻²⁵ Further development of these advanced applications requires controlling the physical and chemical properties of the objects produced. 3D printing methods based on photo-polymerization like stereolithography (SLA) yield higher resolution structures in a shorter time than other techniques, and hence are among the preferred approaches for additive manufacturing.^{26,27} Because these methods are based on site-selective polymerization of

1
2
3 photo-active monomers, they can include molecular diversity either by variation in
4
5 monomer structure (*i.e.* changes in carbon backbone, inclusion of additional functional
6
7 groups) or by combination of different monomers (*i.e.* co-polymerization).^{22,27-43} This
8
9 diversity may hold the key to adjusting physical and chemical properties of multifunctional
10
11 3D printed architectures.
12
13
14
15

16
17 Nonetheless, developing resin compositions that produce three-dimensional structures
18
19 with target chemical and physical characteristics can be expensive and time-consuming.
20
21 These limitations are due to the conventional hardware setup of most SLA printers, which
22
23 are commonly designed to use a single batch of resin per printing cycle in a relatively
24
25 large volume tank (typically 150 mL). Inspired by a recent success in screening resins for
26
27 inkjet printing,⁴⁰ we aimed to develop a direct screening approach for SLA 3D printing.
28
29 Here, we introduce a high throughput screening approach consisting of
30
31 compartmentalizing the build platforms and resin tanks of commercial SLA printers. This
32
33 methodology allowed identification of active resin compositions by directly 3D printing
34
35 functional structures. It also enabled production of a library of 3D printed materials with
36
37 a wide spectrum of surface hydrophilicities/hydrophobicities and a library of 3D printed
38
39 metal acrylates. The metal acrylate library was then screened to identify 3D printed
40
41 structures that were catalytically active in the selective conversion of benzyl alcohol to
42
43 benzaldehyde. More complex compositions were obtained by combining the

hydrophobic resins with the metal-containing resins to 3D print multifunctional architectures that displayed even higher activity for the same reaction.

EXPERIMENTAL

Materials.

Acetonitrile, cerium trinitrate hexahydrate, chromium trinitrate nonahydrate, cobalt dinitrate hexahydrate, copper diacetate monohydrate, iron tri(acetylacetonate), palladium dinitrate, gold trichloride trihydrate, erbium trinitrate pentahydrate, iridium trichloride, zinc dinitrate hexahydrate, allylamine, butyl, isobutyl, hexyl, 2-ethylhexyl, isodecyl, octadecyl, and lauryl acrylates, acrylic acid, bis(2,4,6-trimethylbenzoyl)-phenylphosphine oxide (BAPO), tetramethyl-1-piperidinyloxy (TEMPO), poly(ethylene glycol) diacrylate (PEGDA), benzyl alcohol, propionitrile, and butyronitrile were acquired at Sigma-Aldrich. Antimony trichloride, nickel dinitrate hexahydrate, magnesium diiodide, bismuth trinitrate pentahydrate and cobalt dinitrate were bought at Fischer Scientific. All reagents were used without further purification.

Fused Filament Fabrication (FFF).

Computer aided designs were produced with OnShape (Cambridge, MA, USA) and converted into STL format. The resin tanks and platform matrices were manufactured using polypropylene filament in a Makerbot Replicator 2x™ (New York City, NY, USA). The size of the resin tanks in the 4×4 matrix was 25×25×6 mm each.

Polydimethylsiloxane (PDMS) layer.

To help the peeling process during printing, a layer of PDMS was applied to the bottom of the compartmentalized tanks. Following the manufacturer recommended ratios, 40 g of 10:1 ratio of the Sylgard® 184 two-part solution was prepared and 2 mL from this mixture were added to each tank. The tanks containing PDMS were cured for 24 h in an oven at 50 °C. The cured PDMS-covered tanks were then ready for use as reservoirs for the resins.

Parent resin preparation.

The parent resin consisting of acrylic acid and PEGDA was prepared as reported before.²²

Hydrophobic resins.

The parent resin was mixed with each acrylate in varying ratios according to Table S1. For allylamine the mixture (allylamine: acrylic acid mole ratio 0.13) was prepared in an ice bath to prevent heat evolution and avoid pre-polymerization. The combinations were thoroughly mixed in a homogenizer (14 000 rpm, 5 min), and poured into the low volume resin tanks adapted to a FormLabs Form 1+™ 3D printer (Somerville, MA, USA).

Metal containing resins.

5 mL of the parent resin was mixed with 0.11 mmol of the respective metal salt and sonicated until complete dissolution of the metal salts (Table S2). The solutions were poured into the low volume resin tanks adapted to the FormLabs Form 1+™ 3D printer.

Surface functionalization of 3D printed objects.

A 3D printed cube was added to a methylene chloride solution of N,N'-Dicyclohexylcarbodiimide (48 mM, 5 mL) in a 20 mL vial and set in an orbital shaker (1 h, 300 rpm). 0.15 mmol of the respective amine (i.e. oleylamine, isopropyl amine or *tert*-butylamine) were then added and the vial was shaken for 16 h more. The printed cubes were then thoroughly washed with methylene chloride and dried before measuring the water contact angle.

SLA 3D printing.

Computer aided designs were produced with OnShape (Cambridge, MA, USA), converted into STL format, and printed in the FormLabs Form 1+™ 3D printer. The settings used for non-metal containing resins were: *laser power*: 62 mW, *first layer passes*: 10, *other layer passes*: 2, and *early layer passes*: 2. For metal-containing resins the parameters were: *laser power*: 62 mW, *first layer passes*: 10, *other layer passes*: 5, and *early layer passes*: 5. The residual non-polymerized resin was extracted from the 3D printed solids by soaking in acetone for 5 min. The solids were then cured in a Rayonet photo-reactor ($\lambda = 320$ nm, 20 min).

Oxidation of benzyl alcohol.

A 3D printed metal-polymer composite hollow cube was introduced into a 5 mL vial containing a solution of benzyl alcohol (20 μ L, 0.19 mmol) and Tetramethyl-1-piperidinyloxy radical (TEMPO, 12 mg, 76 μ mol) in acetonitrile (1 mL). The vial was then

1
2
3 crimped with a silicon/aluminum cap, added a stir bar and the solution was stirred at 100
4
5 °C and 200 rpm for 6 h. A 10 μ L aliquot was diluted in ethanol (1 mL) and analyzed by GC-
6
7 MS (Agilent 7890A, 5975C, HP-5MS column). The program initiated at 60 °C, a
8
9 temperature ramp of 5 °C min⁻¹ was applied until reaching 150 °C. This was followed by a
10
11 second ramp of 20 °C min⁻¹ until 280 °C, after which the temperature was held constant
12
13 for 10 min. The reactions were run in parallel using an aluminum heating block reactor.
14
15 Catalytic activity screening was based on the relative intensities of benzaldehyde (ca. 5.15
16
17 min retention time) to benzyl alcohol (ca. 5.95 min retention time) peaks, and selection
18
19 criteria were established as <5%, 5-10% and >10% corresponding to low, moderate and
20
21 high catalytic activity. Decane was used as internal standard for calculating actual
22
23 conversion values (as opposed to screening experiments). To evaluate the effect of solvent
24
25 polarity on reactivity acetonitrile was replaced with propionitrile or butyronitrile.

54 RESULTS AND DISCUSSION

55
56
57
58
59
60

First, we designed a high throughput block (HTB) adaptor set consisting of a 4×4 matrix of build platforms that could be attached to the z-stage of a Formlabs 1+™ 3D printer, and a fitting matrix of 4×4 low volume (2 mL) resin tanks (**Figure 1a, b**). This configuration was chosen to maximize the number of resin tanks for the dimensions of the 3D printer. However, the dimensions and distribution of the tanks and platforms can be adapted to any target size and configuration (Figure S1). The adaptors were then produced by fused filament fabrication (FFF) using a polypropylene (PP) filament in a Makerbot Replicator 2x™ 3D printer. The 4×4 matrix resin tanks were designed to be 25×25×6 mm each. To facilitate peeling of the printed layers, the resin tanks were coated and cured with a 3 mm polydimethylsiloxane (PDMS) layer (Sylgard® 184 silicone elastomer) as a pre-printing process. To prevent leakage during the curing of PDMS the 4×4 resin tanks matrix was fixed onto a Z-vat resin tank using hot melt adhesive (Ad Tech™). Aluminum plates were added to the build platforms to ensure adhesion of the 3D printed objects (**Figure 1c**).

Using the custom 4×4 HTB we 3D printed a library of 32 materials from resins containing the parent mixture (acrylic acid, BAPO and PEGDA) and acrylate esters of varying chain lengths and branching, or allylamine. The mole ratios of acrylate esters or allylamine to acrylic acid were varied from 0.05 to 0.7 (**Table S1**). The resins were 3D printed as hollow cubes (7 mm sides, **Figure S2**) so that material hydrophobicity could be assessed by measuring water contact angles on their flat surfaces (**Figure S3-S11**).

Figure 1. STL design of a) build platform, b) resin tanks and c) complete 4×4 set up for high throughput block (HTB) adaptor.

The parent resin, containing only acrylic acid and PEGDA, had a water contact angle of 42°, characteristic of a hydrophilic surface. The hydrophilic character is likely due to the carboxylic acid moieties on the surface of the 3D printed polymer.²² Incorporation of linear acrylate esters in the C₄ to C₁₂ range resulted in a more hydrophobic surface with a moderate increase in the water contact angle to about 65° at ca. 0.1 acrylate ester : acrylic acid (AE : AA) molar ratios (Figure 2a). The larger contact angle indicates that the hydrocarbon chains of the esters may be exposed on the surface of the objects. A larger increase to about 80° was observed when using the C₁₈ ester at 0.1 AE : AA molar ratio. The larger effect of C₁₈ suggests that in addition to being exposed on the surface, its long hydrocarbon chain may be covering some of the hydrophilic surface carboxylates.

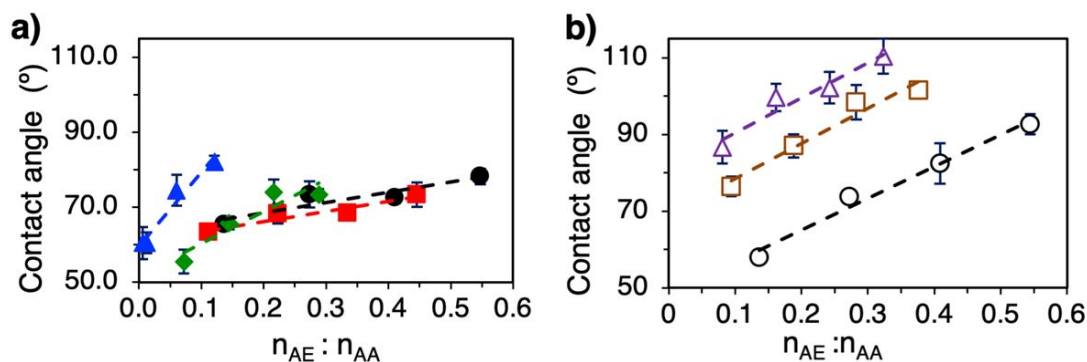

Figure 2. Changes in water contact angle with the amount of acrylate esters (AE) relative to acrylic acid (AA) used in the resin for a) linear (black circles = butyl, red diamonds = hexyl, green squares = lauryl, blue triangles = octadecyl) and b) branched AE (black circles = isobutyl, brown squares = 2-ethylhexyl, purple triangles = isodecyl). Error bars correspond to the standard deviations of two measurements.

The water contact angles of the 3D printed materials displayed a linear dependence on the amount of ester in the monomer mixture, indicating that the surface density of the hydrophobic moieties is proportional to their concentration in the resin. While the rate of increase in contact angle with AE : AA molar ratio was very similar for C_4 and C_6 , it was about 3 and 7 times larger for C_{12} and C_{18} respectively. It must be noted that the longer chain esters had a lower solubility in the resin which limited the amount that could be effectively incorporated into the 3D printed objects. Analysis of the water contact angles of the cubes 3D printed with branched AE monomers indicated a more dramatic effect on surface hydrophobicity: isobutyl acrylate, 2-ethylhexyl acrylate and isodecyl acrylate reached maximum contact angles of 93°, 102° and 110° respectively (**Figure 2b**).

In contrast to the enhanced hydrophobicity produced by alkyl acrylate monomers, the use of allylamine as a co-polymer led to 3D printed objects with higher hydrophilicity than that obtained with the parent resin. For example a resin with allylamine : AA molar ratio 0.13 gave a solid with a water contact angle of 17° (**Figure 3**). The enhanced hydrophilicity is likely due to proton transfer between the amine and the carboxylic acid groups resulting in a zwitterionic surface.⁴⁴

Figure 3. Variations in the wettability of 3D printed resins as a function of the co-monomer included in its composition (mole fractions of co-monomers relative to acrylic acid: isodecyl acrylate (IDA) 0.32, hexyl acrylate (HA) 0.45, allylamine (Aam) 0.13. Error bars correspond to the standard deviations of two measurements.

An additional way to modify the surface hydrophobicity of 3D printed AA resins is by reacting the pendant carboxylic acids with alcohols or amines. We evaluated this post-printing method using carbodiimide to activate surface carboxyls for coupling with isopropyl, tert-butyl and oleyl amines. Bond formation was confirmed by the emergence

of the characteristic amide bands (1630 cm^{-1} and 1550 cm^{-1}) in the infrared spectra of the 3D printed structures (**Figure 4**). Even though the same amounts of amine (0.15 mmol) were added to each of the 3D printed cubes, FTIR showed large differences between them. While the cubes modified with small amines (tert-butyl- and isopropyl-amine) had more intense 1550 cm^{-1} (amide II) than 1720 cm^{-1} (AA and PEGDA carbonyl) bands, the cubes modified with oleylamine had a much more intense 1720 cm^{-1} than 1550 cm^{-1} band. In spite of their lower ratio of amide to carboxyl/ester signal, the oleylamine-modified cubes produced a significantly larger water contact angle (123°) than those modified with isopropylamine and tert-butylamine (90° and 73° , respectively). Importantly, this post-printing modification approach can be combined with the co-polymerization method to produce multifunctional three dimensional objects.

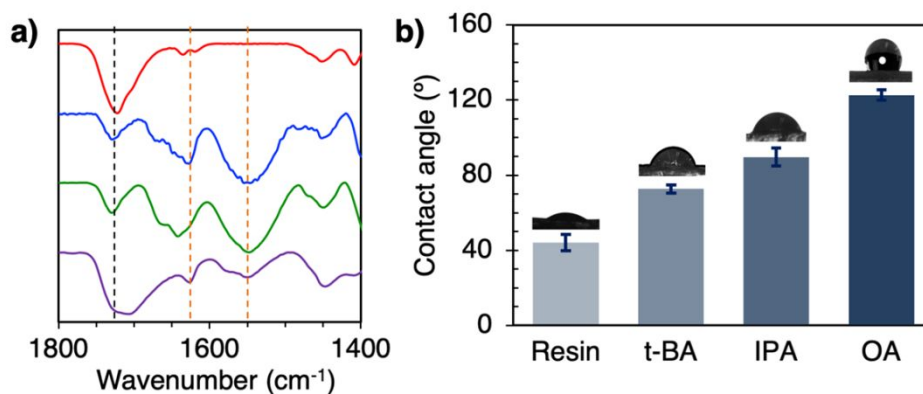

Figure 4. a) Attenuated total reflectance infrared spectra of 3D printed structures before (red) and after grafting with tert-butylamine (blue), isopropylamine (green) and oleylamine (purple). Discontinuous lines correspond to PEGDA and AA carbonyl (black), and amide I and II (orange) bands. b) Water contact angles of 3D printed surfaces

modified with non-polar groups. t-BA = t-butylamine, IPA = isopropylamine, OA = oleylamine. Error bars correspond to the standard deviations of two measurements.

We have recently demonstrated that 3D printing by SLA can produce architectures with intrinsic catalytic activity. Here, we used the HTB adaptor to evaluate 16 metal salts as potential precursors for 3D printed catalysts. First, we dissolved the salts (0.11 mmol) in a resin consisting of PEGDA and AA (5 mL resin, 11.6 and 204 mmol respectively). The resins were then 3D printed to form hollow top- and bottom-less cubes (4 faces, 8×8 mm sides with 0.5 mm thick walls, Figure S12). This simple topology allowed rapid printing that in turn facilitated quick adjustments of the parameters to the metals' properties. For example, because the metal salts had some absorbance at the laser wavelength (405 nm, Figure S13) they required a larger number of laser passes to polymerize in an effective and controlled fashion (5 passes at 62 mW laser power compared to only 2 passes for the normal resin). The 0.5 mm walls still provided a large surface to volume ratio (4.25 : 1) to expose the metal catalyst and enable rapid screening for activity. A large surface to volume ratio is especially relevant because the polymeric matrix has low porosity and a penetration depth limited to ca. 70 μm .²² The products were designated as M-HC, where M represents the metal used. Interestingly, heating the 3D printed Ag-HC and Au-HC at 40 °C for 1h, led to a change from colorless to brown and purple, respectively. The development of color can be ascribed to nanoparticle formation, as previously shown by Fantino et al.^{31,45,46} and Chibac et al.⁴⁷ No changes in appearance were observed for the

1
2
3 remaining M-HC upon heating at 40 °C. Absence of signals in the XRD of the 3D printed
4
5 solids between 10 and 90 2 θ ° further suggested lack of crystalline particles formation.
6
7

8
9 The M-HC were then screened as catalysts for the conversion of benzyl alcohol into
10
11 benzaldehyde. The selective oxidation of primary alcohols to aldehydes is relevant
12
13 because of the ubiquity of these functionalities in active principles of several
14
15 pharmaceuticals, fragrances, dyes, and agrochemicals.^{48,49} Traditionally, these reactions
16
17 require stoichiometric amounts of toxic, expensive and corrosive oxidizing agents like
18
19 DMSO/acyl chloride combinations,⁵⁰ hypervalent iodine,^{30,51} or heavy metals.⁵²
20
21 Consequently, supported transition metal ions have been investigated as potential
22
23 catalysts for this transformation with the aim of conducting a greener process.⁵³ To screen
24
25 for potential catalytic activity the M-HC were added to a mixture of benzyl alcohol (20 μ L,
26
27 0.38 mmol) and TEMPO (12 mg, 0.076 mmol) in acetonitrile (1 mL), sealed with a silicone
28
29 septum, and heated to 100 °C for 6 h in a parallel reaction block (200 rpm). The reaction
30
31 mixtures were then analyzed by GC-MS. Comparison of the relative intensities of
32
33 benzaldehyde to benzyl alcohol peaks indicated some activity for Bi, Co, Er, Ir, Mg and Sb
34
35 (5-10% relative intensity), moderate for Ce, Cr, Ni and Zn (10-15%), and significantly
36
37 higher for Cu (25%) (Table S2). The remaining M-HC, as well as a HC with no metal salt
38
39 embedded, did not show any catalytic activity under these reaction conditions.
40
41 Considering Cu-HC produced the highest benzaldehyde levels in the screening, we used
42
43 this metal for further catalyst 3D printing studies. While some copper species have already
44
45
46
47
48
49

59
60

1
2
3 been reported as active for this reaction,⁵⁴⁻⁶² there are no previous reports of the selective
4
5
6 oxidation of alcohols to aldehydes using Zn or Er salts co-catalyzed by TEMPO.
7

8
9 We then explored how the topology of 3D printed Cu-based catalysts determined the
10
11 amount of surface area exposed and thereby affected conversion. Importantly, because
12
13 the 3D printed polymers are not porous,²⁶ their surface areas were not measured by
14
15 nitrogen physisorption (typical BET surface areas lower than 1 m² g⁻¹) but estimated based
16
17 on macroscale topology. Therefore, we 3D printed a series of triply periodic minimal
18
19 surface (TPMS) constructs. These surfaces consist of two interpenetrating meandering
20
21 paths that lack self-intersections and fill up space in a continuous fashion.⁶³⁻⁶⁶ The 3D
22
23 printed TPMS structures were: Chmutov octic, diamond-1, diamond-3, gyroid, Schoen-I-
24
25 6, Schoen-manta and Schwarz P (**Figure 5**).⁶⁷ To include a low surface structure we also
26
27 3D printed a hypercube model. While these intricate catalyst-containing geometries are
28
29 too difficult to manufacture by conventional methods, 3D printing allows fast and easy
30
31 production, and even modifications to each of them at any desired scale. The 3D surfaces
32
33 were designed and scaled to an 8×8×8 mm cubic volume that fit a test tube leaving space
34
35 for a magnetic stir bar (**Figure S14**). The benzyl alcohol oxidation reactions were
36
37 performed for 21 h at 100 °C and revealed differences in conversion between the 3D
38
39 printed catalyst architectures. Plotting conversion versus the surface area of the structures
40
41 (calculated with 3Dtool softwareTM) indicated that all the structures had the same intrinsic
42
43 activity, and the differences in performance were mainly due to the amount of surface
44
45

60

provided by the specific topology (**Figure 6a**). This result demonstrates that 3D printing can be employed to improve chemical conversions by translating optimized surface packings into active three dimensional catalysts.

Figure 5. STL designs of complex geometries and the corresponding 3D printed Cu-containing catalysts: a) Hyper cube, b) hollow cube, c) diamond-1, d) Chmutov Octic, e), Schoen-I-6, f) Schoen-manta, g) diamond-3, h) Gyroid, and i) Schwarz P (primitive), minimal surfaces. All cubes are designed to have 8 mm sides.

Because low polarity environments can increase conversion in the aerobic oxidation of alcohols catalyzed by metals,⁶⁸⁻⁷⁰ we tested the performance of the most active 3D printed

geometry (Cu-Schwarz P) in three solvents of different polarities (acetonitrile: $\epsilon = 37.5$, propionitrile: $\epsilon = 27.7$, and butyronitrile: $\epsilon = 20.7$). Our results confirmed an inverse relationship between the solvents' dielectric constants and benzyl alcohol conversion (**Figure 6b**). This dependence of conversion on polarity suggested that the performance of Cu-Schwarz P topology could be improved by increasing the hydrophobicity of the 3D printed material using the approaches described before. Therefore, we 3D printed a series of Cu-Schwarz P structures using resins that included different acrylate esters with varying hydrophobicities. In addition to the unmodified resin (contact angle 44°) we used resins with ester modifiers having the following $n_{\text{modifier}}: n_{\text{resin}}$ ratios: of 0.14 for butyl acrylate, 0.30 for 2-ethylhexyl acrylate and 0.33 for isodecyl acrylate. These modified resins gave contact angles of ca. 65° , 100° , and 110° , respectively. Using the modified Cu-Schwarz P-materials as catalysts for the benzyl alcohol oxidation in acetonitrile resulted in a linear dependence of conversion on their water contact angles (**Figure 6c**). The resulting trend is consistent with the one observed using solvents of varying dielectric constants, i.e. higher hydrophobicity leads to improved oxidation activity, with the isodecyl-Cu-Schwarz P being ca. 60 % more active than the parent Cu-Schwarz P catalyst. These results demonstrate that the immediate environment of the catalytic Cu sites in the materials 3D printed with acrylate esters was dominated by the components of the original resin rather than the reaction solvent, and prove that catalytic performance can be improved both by adjusting surface topology and chemical composition of the 3D printed catalysts.

Figure 6. a) Dependence of the apparent catalytic activity of 3D printed Cu-containing complex geometries on their surface areas. Catalytic activity of b) 3D printed Cu-Schwarz P topologies in solvents with increasing polarity (acetonitrile, propionitrile, butyronitrile), and c) 3D printed Cu-Schwarz P topologies prepared from resins with varying hydrophobicities (solvent: acetonitrile). Reaction conditions: 2 mL solvent, 0.15 mmol TEMPO, and 0.76 mmol benzyl alcohol stirred at 100 °C for 21 h. Error bars are the standard deviations of three catalytic conversions.

CONCLUSIONS

This work presents a method to increase the throughput of commercial SLA 3D printers and enable screening of functional 3D printable resins. The high-throughput block (HTB) adaptors consisting of arrays of miniaturized build platforms and resin tanks can be custom designed and 3D printed to suit the needs of any target application. The approach proved useful for producing a series of 3D printed materials with varying surface hydrophobicities and allowed establishing structure-property relationships between the

1
2
3 molecular structure of monomers and the hydrophobicity of solids. While the
4
5 hydrocarbon chain length of the acrylate esters increased the hydrophobicity of the 3D
6
7 printed surfaces, chain branching resulted in a much larger effect. The HTB were also used
8
9 to produce a series of 3D printed metal-containing polymers that were screened as
10
11 potential catalysts in the selective oxidative conversion of benzyl alcohol to benzaldehyde,
12
13 leading to the discovery of new TEMPO co-catalysts with moderate (Ce, Cr, Ni, Zn), and
14
15 mild activity (Bi, Co, Er, Ir, Mg, Sb). In addition, we used the HTB to 3D print a series of Cu-
16
17 containing complex structures and demonstrated the dependence of catalytic conversion
18
19 on the amount of surface that can be efficiently packed in a given volume. The Schwarz P
20
21 topology gave the best catalytic activity, consistent with its highest surface area. Finally,
22
23 because the catalytic activity of Cu in the reaction of benzyl alcohol to benzaldehyde
24
25 increases with decreasing solvent polarity, we modified the surface chemistry of Cu-
26
27 Schwarz P with acrylic esters and demonstrated that the activity increased with the
28
29 materials' surface hydrophobicity, the largest activity enhancement being ca. 60 % using
30
31 an isodecyl acrylate-containing resin. This result suggests that the surface properties of
32
33 3D printed catalysts can ultimately determine the performance of the active sites, and that
34
35 this approach is capable of directly producing multifunctional materials with tunable
36
37 structure and composition.
